ABSTRACT

In recent decades, steroid abuse has become very popular and widespread among professional and recreational athletes. The aim of this study was to examine the chronic effects of training combined with high doses of nandrolone decanoate on cardiac muscle tissue. The study included 32 Wistar albino rats divided into 4 groups: control (T-N-), steroid (T-N+), exercise-training (T+N-) and exercise plus steroid (T+N+) groups. The T+N- and T+N+ group swam for 4 weeks, 1 hour per day, 5 days per week. The N+ (nandrolone positive groups) received nandrolone decanoate (20 mg/kg) once per week, subcutaneously. After 4 weeks of training, the rats were sacrificed. Heart biopsy specimens were routinely fixed and embedded in paraffin. Five-micrometre thick sections were stained with haematoxylin and eosin (H/E) and Masson-Trichrome dyes. Captured microscopic images were processed by special software for image analysis to quantify results. Our results showed that the combination of nandrolone and training causes left ventricular wall thickening of 30%. Average cardiac muscle cell longitudinal diameter was increased by 6% in the T-N+ group, by 16% in the T+N- group and by 25% in the T+N+ group. The cross sectional muscle cell area was increased in the T+N+ group by 33%. Heart collagen content was increased in the nandrolone group compared to the control group by 261%. Collagen content was decreased in the T+N+ group by 34%. High doses of AAS induced left ventricle hypertrophy and excessive heart collagen deposition.

Keywords: nandrolone decanoate, high doses, exercise, heart muscle

INTRODUCTION

Anabolic androgenic steroids (AAS), synthetic derivatives of testosterone, were created as an attempt to synthesize a testosterone-like steroid that would have strong anabolic effects (1). Because of these anabolic effects, AAS became very popular among professional and recreational athletes, even though they were banned in many organized sports (2, 3). The hormone is most frequently used among weightlifters, bodybuilders, swimmers and cyclists to improve their physical performance (4), strength and muscle mass (5). However, these individuals may take doses of up to 100 time higher doses than the therapeutic range, which leads to severe adverse effects on many organ systems (6).

Nandrolone is a derivate of 19-nortestosterone and is most often administered in the form of depot preparations. Today, it is the one of the most popular AAS among athletes. It has a stronger anabolic effect than testosterone, but with long-term usage (7), severe adverse effects such as structural and functional alterations of the liver and even hepatocellular adenoma can be detected (8). Furthermore, chronic abuse of AAS can lead to pathological left ventricular hypertrophy via androgenic receptors (9) located in the cytoplasmic compartment of the cardiac muscle cells (10, 11), as well as abnormalities of impulse conduction and contractility (12, 13). Studies have shown that abuse of AAS can induce hypertrophy of the left ventricle with disproportionate accumulation of extracellular collagen and interstitial fibrosis (14-17). Previous reports have further shown that chronic administration of supraphysiological doses of AAS can lead to increased interventricular septum thickness, dilated cardiomypathy, arrythmia, heart failure and sudden cardiac death (9, 14, 18). On the other hand, exercise and endurance training are known to induce significant changes in the morphology of the heart, including increased left ventricular chamber size, wall thickness and increased mass of the heart, known as an “athlete’s heart” (19). This is a balanced and reversible physiological modification that is followed by necessary neovascularization because muscle hypertrophy occurs as a result of the adaptation of the cardiac muscle to increased physical activity (20).

A review of available literature showed that majority of the studies aimed at revealing the effects of AAS on cardiac muscle tissue (with or without training) were designed to investigate the influence of supraphysiological doses (up to 10 mg/kg) of steroids on the heart (5, 14, 17, 21). However, considering that some individuals, in attempt to rapidly increase their muscle mass and performance, are taking up to 20 mg/kg of AAS, we wanted to gain a better understanding of the effects on cardiac muscle tissue morphology of high-dose nandrolone decanoate administered either alone or in combination with training over a short-term interval.

MATERIAL AND METHODS

Experimental animals

This study included 32 male Wistar albino rats (10 weeks old, weighing 220-280 g). Rats were housed in collective cages (eight rats per cage). Food and water were provided ad libitum. The room temperature was kept at 25±1°C with 12-h alternating light and dark cycles. The rats were randomly divided into four groups: T-N- (sedentary rats with no administration of nandrolone decanoate or exercise training; control group), T-N+ (sedentary rats with weekly administration of nandrolone decanoate (depot preparation, 20 mg/kg s.c. during a period of 4 weeks), T+N- (exercising rats (swimming 1 h/day) with no administration of nandrolone decanoate) and T+N+ (exercising rats (swimming 1 h/day) with weekly administration of nandrolone decanoate depot preparation 20 mg/kg s.c. during a period of 4 weeks). Over the course of 4 weeks, the steroid and exercise-training plus steroid group received nandrolone decanoate (DECA DURABOLIN®, Organon, Holland) administered by subcutaneous injection once per week in doses of 20 mg/kg. The initial and final body weights (BW) and heart weight (HW) were measured. During the 4 weeks, rats were swimming in a pool of 120 x 80 x 50-cm length/depth/width) for 1 hour per day, 5 days per week. The swimming was performed every exercise day starting at 9 a.m. The water temperature was 37°C. After the experimental period, the rats were sacrificed. After short-term anaesthesia (ketamine 100 mg/kg and xilazid 10 mg/kg), the animals were premedicated with heparin as an anticoagulant and were sacrificed by cervical dislocation (Schedule 1 of the Animals/Scientific Procedures, Act 1986 UK), and their hearts were surgically removed for histological examination. This protocol was approved by the Ethics committee, Faculty of Medical Science, University of Kragujevac.

Histological and image analysis

The isolated rat hearts were halved so that the left and right ventricular walls were fully exposed. The organs were fixed in 4% formalin, routinely processed and embedded in paraffin. Sections, 5 µm thin, were stained with H/E, for the visualization of tissue structures, and with Masson-Trichrome dye for collagen detection and quantification. Images of tissue sections were captured with a digital camera attached to the Olympus BX51 microscope. Morphometric analysis was performed by calibrated Axiovision software (Zeiss, USA), as well as with Image Pro-Plus (Media Cybernetics, USA). All measurements were made in triplicate and average values were considered exact. From each half of the heart, 100 serial tissue sections were made. Odd sections were stained with H/E, and even ones were stained with Masson-Trichrome. Cross-sectional area, longitudinal-section diameter measurement of the cardiac muscle cells and collagen segmentation were performed.
Our findings showed that both nandrolone and exercise affected the left ventricular wall. Increased thickness was observed in all experimental groups, and the percentage of thickening ranged from 6% (only nandrolone administration) to almost 30% (nandrolone and training together) compared to the control group (Table 2). Exercise only also led to a greater degree of wall thickening (16%) than that induced by nandrolone administration alone (Fig 1A). Low-magnification overview of the left ventricular wall revealed that the thickening almost exclusively involved myocardium and did not significantly affect the other layers of the heart. Considering that the myocardium is mostly composed of contractile heart muscle cells, our results, unsurprisingly, showed a marked change in their diameter. Both longitudinal section diameter (LD) and cross-section area (CSA) were increased in all experimental groups compared to the control group. Training alone induced increases in the size of heart muscle cells of 21% (LD) and 23% (CSA) (Fig 1b and 1c). There was a similar tendency in the results of left ventricular thickening, with average values positioned just between those of the T-N+ group and T+N+ group.

**DISCUSSION**

Anabolic androgenic steroids (AAS), although banned in sports, are still widely used by professional and recreational athletes who intend to quickly gain muscle mass and improve cardiovascular system performance. In the available

Table 2. Measurement of morphometric parameters and heart collagen content, mean ±SD
the majority of the heart wall is composed of cardiac muscle cells, our findings related to the measurement of cell diameter confirm these findings. Unfortunately, we were unable to find sufficient data to compare the direct effects of various doses of steroids on cardiac myocyte size. A study published by Ren et al (2012) showed that steroids alone can induce cardiomyocyte hypertrophy (up to 35% at 100nM of dexamethasone) a dose much higher than that used in our study (15% increase with nandrolone alone). The divergence may be the result of different study design (e.g., their study was performed in cell culture conditions); therefore, the doses of the hormones may not be comparable. Nevertheless, the increases in cardiomyocyte size observed in our experiment were consistent with the ventricular wall thickening also observed. This was particularly obvious when the cross-area of the heart muscle cells was measured.

Another adverse effect of nandrolone abuse is increased heart collagen content. Our results showed that the most significant collagen deposition between cardiac myocytes was observed in the animals that were treated with nandrolone alone. Furthermore, the lowest collagen content was observed in the hearts of the animals that were exposed to training alone or in animals exposed to both nandrolone and training. This proves that training is the most significant way to reduce the collagen-related adverse effects of steroids. These results coincide with the findings of previous studies (5) but are in conflict with the findings of Tano et al (2011), who stated that the collagen content is highest in hearts of animals that were exposed to combined nandrolone and training. On the other hand, our results are in accordance with those of Franquini et al (2013). They found that nandrolone alone, administered in the same dose as in our study but twice a week, caused a
10-fold increase of heart collagen. The increase in heart collagen content observed in our study among animals exposed only to nandrolone was 2.5-fold compared to controls (261% increase). These significant differences in results only show that further investigation is needed on the effects of AAS on heart collagen deposition. Nevertheless, our findings and those of Franquini et al lead us to the conclusion that dose-dependent heart collagen deposition is not limited, even at the highest doses. In contrast to the nandrolone effect, our study showed that training induces a decrease in collagen content of the heart. Similar findings were reported by other researchers (5), which demonstrates that exercise can minimize the adverse collagen deposition effect of steroids.

In general, our study demonstrates that nandrolone abuse has serious adverse effects on heart morphology. High doses of steroids, used by some misinformed athletes during the training process, induces significant collagen deposition and heart fibrosis, but does not significantly increase left ventricular thickness compared to lower supraphysiological doses.
